#### ABSTRACT

Ē

This paper summarizes studies to determine the stability of water-in-oil emulsions of over 100 oils, including one emulsion from the ERIKA spill. Emulsions were analysed after one year of storage to examine the change in properties after that time.

These studies have confirmed that the stability of emulsions can be grouped into three categories: stable, unstable and meso-stable. Water can also reside in oil as viscous forces. These have been distinguished by physical measures as well as visual differences. The viscosity of a stable emulsion at a shear rate of one reciprocal unstable emulsion usually has a viscosity no more than about 20 times greater than that of the starting oil. A stable emulsion has a significant elasticity, whereas an and unstable, but breaks down within a few days of standing. The usual situation is water suspended in oil by viscous forces alone, is also evident. Very few emulsions observations.

ᢓ

The properties of the starting oil are the important factor in determining what type of water-in-oil state is produced. Composition and property ranges are given for the starting oil to form each of the water-in-oil states. Important property factors are the asphaltene content, resin content, and starting oil viscosity.

### 0 Introduction

The most important characteristic of a water-in-oil emulsion is its "stability". The reason for this importance is that one must first characterize an emulsion as stable (or unstable) before one can characterize the properties. Properties change very significantly for each type of emulsion. Until recently, emulsion stability has not been defined (Fingas et al. 1998). Therefore, studies were difficult because the end points of analysis were not defined. This paper continues studies of the stability of water-in-oil emulsions and defines characteristics of different stability classes. Four 'states' that water can exist in oil will be described. These include: stable emulsions, meso-

---

The cmulsions, unstable emulsions (or simply water and oil) and entrained water.

The four 'states' are discriminated by visual appearance as well as by rheological absurcs.

Mesostable emulsions are emulsions that have properties between stable and table emulsions (really oil/water mixtures) (Fingas et al. 1998). It is suspected mesostable emulsions lack sufficient asphaltenes to render them completely le or still contain too many de-stabilizing materials such as smaller aromatics. Associately of the oil may be high enough to stabilize some water droplets for a fold of time. Mesostable emulsions may degrade to form layers of oil and stable alknows. Mesostable emulsions can be red in appearance or black.

Unstable emulsions are those that decompose (largely) to water and oil stly after mixing, generally within a few hours. Some water (usually less than at 10%) may be retained by the oil, especially if the oil is viscous. Entrained of may persist in viscous oils for a period of time. This 'entrained' stage has a till the span, but residual water, typically about 10%, may persist for a long time.

The most important measurements to characterize emulsions are forced illution rheometry studies. The presence of significant elasticity clearly defines their or not a stable emulsion has been formed. The viscosity by itself can be an autor (not necessarily conclusive, unless one is fully certain of the starting oil oxity) of the stability of the emulsion. Colour is an indicator, but may not be emittive. This laboratory's experience is that all stable emulsions were reddish, ne meso-emulsions also had a reddish colour, but unstable emulsions were always colour of the starting oil. Water content is not an indicator of stability and is appropriate that stable emulsions have water that may be present. It should be noted ever that stable emulsions have water contents greater than 70% and that unstable exists or entrained water-in-oil generally have water contents less than 50%. It content after a period of about one week is found to be more reliable than are less stable.

This paper reports on studies of the states of new oils from a previous study over al., 1998) and reports on the analysis of some of the water-in-oil states of them one year after their initial formation. Over 100 oils have been studied to

#### Experimental

Water-in-oil emulsions were made in a rotary agitator and then the rheometric exercistics of these emulsions studied over time. Over 100 oils were used. Oils staken from the storage facilities at the Emergencies Science Division. Series of these oils are given in standard references and will be summarized later in paper (Jokuty et al., 1999). A sample of the oil spilled from the ERIKA, a pile of the emulsion formed in a test tank and a sample of the emulsion recovered a approximately two weeks after the spill, were provided by CEDRE, Brest,

Emulsion Formation - Emulsions were made in an end-over-end rotary mixer octated Design). The apparatus was located in a temperature controlled room at regrees Celsius. The mixing vessels were 2.2 L FLPE wide-mouthed bottles. The mixing vessels were approximately one-quarter full, with 600 mL salt.

water (3.3% w/v NaCl) and 30 mL of the sample crude oil or petroleum product. The vessels were mounted into the rotary mixer, and allowed to stand for several hours (usually four) to thermally equilibrate. The vessels were placed in the rotary mixer such that the cap of each mixing vessel follows, rather than leads, the direction of rotation. The vessels were then rotated for a period of 12 hours at a rate of 55 RPM, or at the specified rate of rotation for the specified time. The vessels were approximately 20 cm in height, providing a radius of rotation of about 10 cm. At the conclusion of the mixing time, the emulsions are collected from the vessels for measurement of water content, viscosity and the complex modulus. The emulsions were stored in the cold room at 15°C for one week, then measured again. The emulsions continue to be stored until measured at a time greater than one year from the time of formation.

Rheology - The following apparatuses were used for rheological analysis: Haake R\$100 RheoStress rheometer, IBM-compatible PC with RheoStress R\$ Ver. 2.10 P software, 35 mm and 60 mm parallel plates with corresponding base plates, and a circulating bath maintained at 15.0 °C. Analysis was performed on a sample spread onto the base plate and raised to 2.00 mm from the measuring plate, with the excess removed using a teflon spatula. This was left for 15 minutes to thermally equilibrate at 15 °C.

Viscosity denoted as "RS100" was measured on an RS100 RheoStress rheometer using a 3.5 mm plate-plate geometry. The shear rate was nominally 1 reciprocal second, and corrected by the Weissenberg equation: corrected viscosity = measured viscosity \* (3+n)/4 where n is the power-law exponent, determined by a frequency sweep in the oscillation mode.

Viscosity denoted as "RV20" is measured on an RV20 with RheoController and M5 measuring head. The concentric cylinder geometry is used, specifically the SV and SV1 cup and spindle combination, at a controlled shear rate of 1 reciprocal second.

Forced Oscillation - A stress sweep at a frequency of 1 reciprocal second was performed first to determine the linear viscoelastic range (stress independent region) for frequency analysis. This also provides values for the complex modulus, the clasticity and viscosity moduli, the low shear dynamic viscosity, and the tan( $\delta$ ) value. A frequency sweep was then performed at a stress value within the linear viscoelastic range, ranging from 0.04 to 40 Hz. This provides the data for analysis to determine the constants of the Ostwald-de-Waele equation for the emulsion.

Water Content - A Metrohm 701 KF Titrino Karl-Fischer volumetric titrator and Metrohm 703 Ti Stand were used. The reagent was Aquastar Comp 5 and the solvent, 1:1:2 methanol:chloroform:toluene. The specific method used was as follows: standardize the titre and blank the solvent. The sample emulsion was stirred to get a relatively homogeneous mixture. A 1 mL plastic syringe was filled with emulsion, trying to avoid free water pockets present in the sample. All but 0.1 mL was ejected; this should have removed most of the free water from the more viscous emulsion. The sample syringe was weighed and injected into the reaction vessel, being careful the sample went into the solution and not onto the vessel walls. The syringe was reweighed and the mass difference entered into the titrator. Titration was initiated. Weight percentage of water was displayed.

Complex Modulus - The complex modulus is a measure of the overall

rea. This combines the elements of viscosity and elasticity for viscoelastic materials ach as water-in-oil emulsions. Since crude oils generally do not possess significant asticity, it has been found that dividing the complex modulus of the emulsion by the recosity of the fresh oil is a useful indicator of the stability of the emulsion, as a thuc greater than 200 generally indicates a stable emulsion.

The complex modulus was measured on an RS100 RheoStress rheometer sing a 35 mm plate-plate geometry. A stress sweep was performed in the range 25 - 1.000,000 mPa in the oscillation mode at a frequency of 1 Hz. The resulting emplex modulus in the linear portion of the range was reported.

## 0 Results and Discussion

hase response (phase angle = 90) is wholly viscous. A phase angle between 0 and 90 e emulsion and the fifth column is the complex modulus which is the vector sum of and appearance and rheological properties. The fourth column is the viscosity of reasurements taken at one week and for those taken at least one year later. nows elements of both, with the relative ratio provided by the tangent. Finally, the a applied stress, providing a relative ratio of the elastic response to the viscous ic clasticity component. Tan(delta) is the tangent to the phase angle of response to runits of force per area (Pa). Column 6 is the tan delta, the ratio of the viscosity to ibstance against the applied stress, combining elements of viscosity and clasticity, ic viscosity and elasticity. The complex modulus represents the total resistance of a he third column is the assessment of the stability of the emulsion based on both ater content of the water-in-oil state is presented. This is repeated for the spanse. An in-phase response (phase angle = 0) is wholly clastic, while an out-ofhe second column of the table is the evaporation state of the oil in mass percent lost hast one year had passed. The rheological data for over 100 oils are given in Table 1. ere stored in a cold room and the rheological properties were re-measured after at The emulsions and mixtures formed in a previous study (Fingas et al., 1998)

Observations were made on the appearance of the emulsions and were used to lassify the emulsions. All of the stable emulsions appeared to be stable and remained atact over seven days in the laboratory. All of the meso-stable emulsions broke after few days into water, free oil and emulsion. The time for these emulsions to break sawn varies from about 1 to 3 days. All entrained water mixtures appeared to have arger suspended water droplets and broke down within hours to an oil and water ayer, with some retention of some water. The appearance of non-stable water in oil cas just that, the oil appeared to be unchanged and a water layer was clearly visible. These values also made in another study on the formation of emulsions (Fingas 2.1., 2000). These show that the emulsions are formed fairly rapidly and that there is

Table 2 shows the summary of the property changes for the different types of mulsions over the three time periods. The most obvious, and largest change is that of after content, and other properties for the meso-stable emulsions between the day of amation and one week later. These values are highlighted in the table. These mulsions break down between these two times, thus all properties are drastically different. The complex modulus stayed about the same or went up for all states etween the one week time period and one year. The value of stability would do so as

well. Other values in the table show changes for the different types, for example, the water content of the unstable mixtures went up between one week and one year. This latter example is based only on a few values and the standard deviation is very high. Overall, the water-in-oil states gained viscosity, values of complex modulus and lost water between each time period. Stable emulsions lost the least amount of water. Only one oil, Arabian Light, refer to Table 1, appeared to lose some stability during the year time period. Its characteristics are now more similar to that a meso-stable emulsion than of a stable, after one year. This is the first and only case of a high decrease in both stability and water content observed for a stable emulsion over a one-year time period.

The oils that were reported in the earlier study (Fingas et al., 1998) were reassessed and Table 3 summarizes the data on these. Table 3 provides the data on the oil properties as well as the parameter called 'stability' which is the complex modulus divided by the viscosity of the starting oil. It is noted from this table that this parameter correlates quite well with the assigned behaviour of the oils. High stability parameters imply stable emulsions and low ones imply unstable emulsions.

Table 4 summarizes the data from Table 3. Table 4 shows that all classes of water-in-oil states (except unstable, which was not included here) increased in stability over the year time period. All lost some amount of water as well during the year time period. Stable emulsions showed the least increase in stability and the least loss of water, probably because these values were both the highest to begin with. Water loss, very slight in the case of stable emulsions, is probably due to drainage of excess water and loss of water during each subsequent analysis procedure. The Arabian Light emulsions were separated from the stable emulsions in calculating the data from Table 4 because their stability after one year was in question.

Table 5 shows properties of the oils in various classes and the properties of the resulting water-in-oil state. Data were averaged from this paper and the previous work (Fingas et al., 1998). This shows that the factor, stability, is capable of discriminating among the various states of water-in-oil studied here. Although there are overlapping ranges, the differences are generally sufficient to act as a single-value discriminator. It is noted that there are different viscosity ranges for the different states. This shows that viscous forces are responsible for part of the stability, but that after viscosity of the starting oil rises to a given point, about 20,000 mPa.s, that meso-stable or stable emulsions are no longer produced.

Table 5 shows that the starting oil properties differ somewhat for oils that form the various states. The oil properties for stable and meso stable are similar. These are oils of medium viscosity that contain a significant amount of resins and asphaltenes. Meso-stable emulsions may form from oils that have higher or lower viscosities than those that might form stable emulsions. Stable emulsions are more likely to form from those oils having more asphaltenes than resins. Entrained water is likely to form from more viscous oils with relatively high densities. Oils of very high or very low viscosities (and densities) are unlikely to uptake water in any form. These oils typically have no asphaltenes or resins (associated with low viscosity and density), or very high amounts of these.

Table 5 also shows that the differences between the four water-in-oil states is readily discernible by appearance and rheological properties. The reddish or brown colour on formation indicates either a stable or meso-stable emulsion, however,

apparent viscosity after one week averages about 1,500 for a stable emulsion, 30 for a meso-stable emulsion, 3 for entrained water-in-oil and unstable show little or no increase. It is noted that apparent viscosity for stable emulsions only, does not decrease after one-week.

There are several other features noted in the summary data presented in Table 5. An examination of the wax content shows that wax content has no relation to the formation of any of these states. There may be some correlation to viscosity but the

emulsion, 45 for a meso-stable emulsion, 13 for entrained water-in-oil and unstable show little or no increase. This difference increases after one week. The increase in

stable emulsions always have a more solid appearance. The increase in apparent viscosity (from the starting oil) on formation averages about 1,100 for a stable

5. An examination of the wax content shows that wax content has no relation to the formation of any of these states. There may be some correlation to viscosity but the specific wax content is not associated with the formation of any state. It is noted that density is associated with the viscosity and somewhat to the state. It is also noted that the water content correlates somewhat with the state. The average water content of stable emulsions is 80 % on the day of formation, of meso-stable - 62, of entrained - 42 and 5 for unstable. One must be cautious on using this as a sole discriminator because of over-lapping ranges. The water content after one week, as would be expected, correlates very highly with the state. This, as was noted above, is accontated by the fact that meso-stable and entrained water-in-oil have separated to a significant degree.

These data indicate that there are 'windows' of composition and viscosity which results in the formation of each of the types of water-in-oil states. The important composition factors are the asphaltene and resin contents. Asphaltenes are responsible for the formation of stable emulsions, however, a high asphaltene content can also result in a high viscosity, one that is above the region where stable emulsions form. The asphaltene/resin ratio is generally higher for stable emulsions. In a previous work by the present author, it was shown that the migration rate of asphaltenes in emulsions is very slow (Fingas et al. 1996). This indicates that in very viscous oils, the migration of asphaltenes may be too slow to allow for the stabilization of emulsions.

One very important question was whether actual emulsions formed at sea would fit this scheme. Emulsion formed in the lab, starting oil and an emulsion formed at sea in the recent ERUKA spill were analysed. The emulsion was stable. The

### Conclusions

relevant to those emulsions produced at spills in the real world

emulsions. Further work will be done to ensure that the laboratory findings are

asphaltene/resin ratio of 0.4. The data from this emulsion fit the parameters of Table 5. Thus, this real world emulsion fits the same parameters as the laboratory

water content was 57.2%, the complex modulus was 480,000 kPa and the tan delta was 1. The asphaltene content was 7 % and the resin content was 16 %, yielding an

Four, clearly-defined states of water-in-oil have been shown to be defined by a number of measurements and by their visual appearance, both on the day of formation and one week later. The difference between these states and the oils that form them are summarized in Table 6.

formation and one week later. The difference between these states and the oils that form them are summarized in Table 6.

The results of this study indicate that the formation of both stable and mesostable emulsions is due to the combination of surface-active forces from resins and

asphaltenes and from viscous forces. There exists a range of compositions and viscosities in which each type of water-in-oil state exist. The difference in composition between stable and meso-stable emulsions is small. Stable emulsions have more asphaltenes and less resins and have a narrow viscosity window. Instability results when the oil has a high viscosity (over about 50,000 mPa.s) or a very low viscosity (under about 6 mPa.s) and when the resins and asphaltenes are less than about 3% each. Water entrainment occurs rather than emulsion formation when the viscosity is between about 2000 and about 50,000 mPa.s. The formation of stable or meso-stable emulsions may not occur in highly viscous oils because the migration of asphaltenes (and resins) is too slow to permit droplet stabilization.

The role of other components is still unclear at this time. Aromatics dissolve asphaltenes and there is a small correlation observed with the stabilities. Waxes have no role in emulsion formation. Density of the starting oil is highly correlated with viscosity and thus shows a correlation with stability.

The state of the final water-in-oil mixture can be correlated with the single parameter of the complex modulus divided by the starting oil viscosity. This stability parameter also correlates somewhat with the non-Newtonian behaviour of the resulting water-in-oil mixture, with the elasticity of the emulsion and also the water content. These properties are more decisive in defining the state one-week after formation. This is because in this interval, all states have largely separated into oil and water except for stable emulsions. The water content retained one-week after the formation process is a very clear discriminator of state.

All water-in-oil water states gain some stability after one year. All lose some water, but generally this is only a small percentage. There appears to be no change in state after one year, with the exception of Arabian light emulsions which lost significant stability indicating that the 'stable' emulsion may be breaking down in about one year.
